Abstract

Recently suggested method of measuring Renyi entropies of multiparticle systems produced in high-energy collisions is presented in the form of a “do-list”, explaining explicitly how to perform the measurement and suggesting improvements in the treatment of the data.

PACS25.75.Gz, 13.65.+i

1 Introduction

A possibility to estimate the Renyi entropies [1] of the multiparticle systems created in high-energy collisions was suggested some time ago by two of us [2]. The method is based on observation of the event-by-event fluctuations or, more precisely, on measurement of coincidences between different events observed in collisions. Being classical in nature, the analysis of [2] could not, however, provide the absolute scale for entropy and thus the obtained numbers suffered from a serious uncertainty. Recently, we published several

†Address: Radzikowskiego 152, 31-342 Krakow, Poland

papers discussing a quantum approach to the same problem [3–5]. This allows to reduce the uncertainties of the classical treatment and to formulate the improvements of the method, leading to a more precise determination of Renyi entropies from data. Since the Renyi entropy gives the lower limit on the Shannon entropy [6], such measurements may provide essential information¹ on the structure of the system produced in high-energy collisions [8].

In the present paper we collect the results of [3–5] in the form of a “do list”, i.e. of an explicit prescription how to perform the measurements and how to estimate the necessary corrections. We spell out explicitly the steps to be taken to implement effectively the results of [3–5]. The importance of the dependence of measurements on discretization of particle momenta and the role of (multi)particle correlations are emphasized. The paper may be considered as an extension of the previous publication with a similar title [9], but it can be read independently.

2 Selection of the phase-space region

As the first step in the process of measurement one has to select a phase-space region in which measurements are to be performed. This of course depends on the detector acceptance as well as on the physics one wants to investigate. The region cannot be too large because for large systems the method is difficult to apply (the requirements on statistics become too demanding). With a statistics of 10^6 events, the region containing (on the average) ≈ 100 or less particles should be possible to investigate. A reasonable procedure seems to be to start from a small region and then increase it until the errors become unacceptable.

Comment: The proposed measurement is *not* restricted to systems with large number of particles. It can be applied to any multiparticle system, e.g., to e^+e^- annihilation, hadron–hadron collisions or peripheral nucleus–nucleus collisions. It was tested for the PYTHIA MC code for pp collisions [10] and recently employed for data on hadron–hadron collisions by the NA22 collaboration [11].

¹For a recent discussion of this point, see [7].

3 Discretization of the spectrum

The selected region in momentum space² should now be divided into bins. The size of the bins is — in principle — arbitrary. It turns out to be convenient to express it in the form

$$\Delta K_x \Delta K_y \Delta K_z = \left[\frac{2\pi}{l^{1/(l-1)}} \right]^{3/2} \frac{\kappa_x}{L_x} \frac{\kappa_y}{L_y} \frac{\kappa_z}{L_z}, \quad (1)$$

where l is the rank of Renyi entropy to be measured, $\kappa_x, \kappa_y, \kappa_z$ are arbitrary (positive) parameters, and L_x^2, L_y^2, L_z^2 are the mean square radii of the system in configuration space, e.g.

$$L_x^2 = \int (X - \bar{X})^2 D(X, Y, Z) dX dY dZ. \quad (2)$$

Here $D(X, Y, Z)$ is the normalized distribution of positions of particle emission points in configuration space.

As seen from (1) the parameter $\kappa \equiv \kappa_x \kappa_y \kappa_z$, is a regulator of the size of the bins used for discretization of the spectrum. Note that κ need not be constant through the selected momentum space. Actually it may be — generally — convenient to vary κ with the position of the bin in momentum space. For example, in case of boost invariant distribution it is reasonable to discretize with bins of equal size in rapidity. The well-known equality $dK_z = E(K) dy$ suggests to take

$$\kappa_z = E(K_z, K_\perp) \kappa_z^{(0)}, \quad (3)$$

where $E(K_z, K_\perp)$ is the particle energy in the considered bin (K_z and K_\perp are the central values in this bin), while $\kappa_z^{(0)}$ is a constant.

Although the value of the measured Renyi entropy does not depend on the choice of κ , it should be emphasized that its selection does influence the accuracy of the measurement.

The number of bins cannot be too large if one wants to keep the statistical errors under control. It follows that (1) restricts the acceptable values of κ and of the size of the momentum phase-space region which one may reasonably investigate at a given statistics of the experiment.

²We use the notation K for momenta and P, W for probabilities.

4 Description of an event

Using this procedure, an event is characterized by the number of particles in each bin, i.e. by a set of integer numbers $s \equiv m_j^{(i)}$, where $j = 1, \dots, J$ (J is the total number of bins) and the superscript (i) runs over all the kinds of particles present in the final state. These sets represent different states of the multiparticle system which were realized in the given experiment. The number of possible different sets is, generally, very large (for 5 bins and 100 indistinguishable particles one obtains about 5×10^6 sets). This is, in fact, the main difficulty in the application of the method. It reflects the fact that the system we are dealing with has very many possible states.

Comment: It should be realized that, in practice, such a description is never complete, i.e., it never describes fully the event (even if the bin width is ignored). Most often some of the variables are summed over. This is the case, e.g., when one measures only charged particles. Then all the variables (i.e. multiplicities and momenta) related to neutral particles are summed over. It may be thus interesting to study *reduced events*, when even some of the measured variables (e.g. particle identity) are summed over (i.e. ignored).

5 Measurement of experimental coincidence probabilities

As explained in [2], the measurement of experimental coincidence probabilities is the basis of the method and therefore the most important step in the whole procedure³.

The measurement consists of the simple counting how many times (n_s) any given set s appears in the whole sample of events. Once the numbers n_s are known for all sets, one forms the sums:

$$N(l) = \sum_s n_s (n_s - 1) \dots (n_s - l + 1) \quad (4)$$

with $l = 1, 2, 3, \dots$. Each sum formally runs over all the sets s recorded in a given experiment, but nonvanishing contributions are given only by those

³The method was adapted [12] to the present context from the original proposal by Ma [13].

which were recorded at least l times⁴. Thus $N(l)$ is the total number of observed coincidences of l configurations and it can be recognized as the factorial moments [14] of the distribution of n_s (in particular, $N(1) = N$, where N is the total number of the events in the sample). The *coincidence probability* of l configurations is thus given by

$$C^{\text{exp}}(l) = \frac{N(l)}{N(N-1)\dots(N-l+1)} \approx \frac{N(l)}{N^l}. \quad (5)$$

Of course $C^{\text{exp}}(1) = 1$. As explained in [2], this ratio is equal⁵ to the $(l-1)$ -th moment of the probability distribution: $C^{\text{exp}}(l) = \sum_s (p_s)^l$.

It is clear that two identical configurations must have the same total number of particles measured in the phase-space region considered, say M . It turns out that to obtain Renyi entropies, it is necessary to determine $C^{\text{exp}}(l)$ for each multiplicity separately. We shall denote these numbers by $C_M^{\text{exp}}(l)$.

The error of $C^{\text{exp}}(l)$ is determined by the error of the numerator in (5). One finds approximately $[\Delta N(l)]^2 \approx l!N(l)$.

6 Renyi entropies

To obtain the Renyi entropies:

$$H(l) = \frac{1}{1-l} \log C(l) \quad (6)$$

it is necessary to determine the *true* coincidence probabilities:

$$C(l) = \text{Tr}[\rho]^l \quad (7)$$

with ρ being the density matrix of the system. $C(l)$ can be expressed in terms of the true coincidence probabilities $C_M(l)$ at fixed multiplicity:

$$C(l) = \sum_M [P(M)]^l C_M(l), \quad (8)$$

⁴Since the number of different sets is very large, most of them shall appear only once or not at all.

⁵The proof follows closely the argument of [14].

where $P(M)$ is the multiplicity distribution⁶.

The relation between $C_M(l)$ and the measured $C_M^{\text{exp}}(l)$ was studied in [3–5]. It can be summarized as follows:

$$C_M(l) = C_M^{\text{exp}}(l) \Lambda_M(l) \Psi_M(l). \quad (9)$$

The correction factors Λ_M and Ψ_M depend on M (this is the reason why $C_M^{\text{exp}}(l)$ must be determined for every multiplicity separately). They are discussed in the next two sections.

7 Estimate of $\Lambda_M(l)$

Denoting the (3M dimensional) normalized momentum distribution by

$$w(K) \equiv e^{-v(K)}, \quad (10)$$

and the size of a bin j by ω_j the correction factor $\Lambda_M(l)$ is given by

$$\Lambda_M(l) = \frac{\sum_j \kappa_j^M \langle [w(K)]^l \rangle_{\omega_j}}{\sum_j \kappa_j^{Ml} [\bar{w}_{\omega_j}]^l}, \quad (11)$$

where the summation extends over all (3M-dimensional) bins and $\langle \dots \rangle_{\omega_j}$ denotes the average over a bin of volume $(\omega_j)^M$, e.g.,

$$\langle [w(K)]^l \rangle_{\omega_j} = \frac{1}{\omega_j} \int_{\omega_j} d^{3M} K [w(K)]^l. \quad (12)$$

We have also introduced the shorthand

$$\bar{w}_{\omega}(K) \equiv \frac{1}{\omega} \int_{\omega} d^{3M} K w(K) = \langle w(K) \rangle_{\omega}. \quad (13)$$

To estimate $\Lambda_M(l)$ we observe that summations in numerator and denominator of (11) can be expressed as integrals over the considered phase-space region. We thus have

$$\Lambda_M(l) = \frac{\int d^{3M} K [\kappa(K)]^M [w(K)]^l}{\int d^{3M} K [\kappa(K)]^{Ml} [\bar{w}_{\omega}(K)]^l}. \quad (14)$$

⁶We remind the reader that M is the number of particles taken into account in the measurement. It need not be identical with the number of all particles measured in the part of momentum space considered in the analysis.

If κ is independent of the bin (i.e. independent of K), this formula simplifies into

$$\Lambda_M(l) = \kappa^{-M(l-1)} \hat{\Lambda}_M(l), \quad \hat{\Lambda}_M(l) = \frac{\int d^{3M}K [w(K)]^l}{\int d^{3M}K [\bar{w}_\omega(K)]^l}. \quad (15)$$

One sees that in this case $\hat{\Lambda}_M(l)$ tends to one if the size of the bins is small enough (i.e. when $w(K)$ can be treated as constant within one bin). Then the value of $\Lambda_M(l)$ is under full control.

If the bins are not small enough, one sees from (14) and (15) that $\Lambda_M(l)$ can be estimated using the MC code appropriate for the given process. For the numerator this is rather straightforward. For the denominator, it is necessary to construct first the “smeared” MC which ignores the difference between the momenta of particles within each bin.

A simpler, but less precise, method is to ignore correlations between particles and write the distribution $w(K)$ in form of the product

$$w(K) = f(K_1) \dots f(K_M), \quad (16)$$

where $f(K)$ is the single-particle momentum distribution.

In this case we obtain

$$\Lambda_M(l) = [\lambda(l)]^M \quad (17)$$

with

$$\lambda(l) = \frac{\int d^3K \kappa(K) [f(K)]^l}{\int d^3K [\kappa(K) \bar{f}_\omega(K)]^l} \quad (18)$$

and thus $\lambda(l)$ can be fairly easily evaluated numerically or even analytically.

8 Estimate of $\Psi_M(l)$

The second correcting factor Ψ_M is given by the formula [4]

$$\Psi_M(l) = \frac{\int d^{3M}K [w(K)]^l \Theta_l(K)}{\int d^{3M}K [w(K)]^l}, \quad (19)$$

where

$$[\Theta_l(K)]^{-1} = \text{Det} \left[1 + \sum_{s=1} a_s(l) [T]^s \right] \quad (20)$$

and

$$a_s(l) = \frac{1}{2^s} \frac{(l-1)!}{(2s+1)!(l-2s-1)!}. \quad (21)$$

T is the symmetric $3M \times 3M$ matrix

$$T_{m\alpha, n\beta} = \frac{1}{L_\alpha} V_{m\alpha, n\beta} \frac{1}{L_\beta} \quad (22)$$

with

$$V_{m\alpha, n\beta} \equiv \frac{\partial}{\partial K_{m\alpha}} \frac{\partial}{\partial K_{n\beta}} v(K). \quad (23)$$

Here $m, n = 1, \dots, M$ label the particles and $\alpha, \beta = x, y, z$ denote the space directions.

It is seen from these formulae that $\Psi_M(l)$ is independent of the bin size and thus cannot be influenced by selection of κ . It does depend, however, on the size of the system in configuration space (L_x, L_y, L_z) . Moreover, as explained in [4], Eq. (19) represents an expansion in powers of L^{-1} and thus can only be trusted if L is large enough, so that $\Psi_M(l)$ is not too different from one⁷.

Note that (21) implies that the sum in (20) is finite, because all $a_s(l)$ vanish for $s \geq (l-1)/2$. In particular for $l = 2$ we obtain $\Theta_2 = 1$ and thus also $\Psi_M(2) = 1$. For the other two practically interesting cases ($l = 3, 4$), the sum reduces to just one term with

$$a_1(3) = \frac{1}{12}, \quad a_1(4) = \frac{1}{4}. \quad (24)$$

Again, a MC code seems to be the best method to estimate $\Psi_M(l)$. Indeed, Eq. (19) can be rewritten as

$$\Psi_M(l) = \int d^M K P_l(K) \Theta(K) = \langle \Theta \rangle, \quad (25)$$

where the probability distribution $P_l(K)$ is defined as

$$P_l(K) = \frac{[w(K)]^l}{\int d^3 K [w(K)]^l}. \quad (26)$$

⁷It is clear that $\Psi_M(l)$ approaches one in the limit of large $L's$.

To construct $\Theta(K)$, however, an analytic formula for $w(K)$ is necessary, as seen from (22) and (23). This may be a difficulty.

If correlations between particles are neglected, the matrix $T_{m\alpha,n\beta}$ is diagonal in (m,n) and the calculation of the determinant in (20) is greatly simplified. We write

$$v(K) = \sum_{m=1}^M u(K_m) \quad (27)$$

and thus

$$V_{m\alpha,n\beta} = \delta_{mn} \partial_{m\alpha} \partial_{m\beta} u(K_m). \quad (28)$$

We shall only consider $l = 3$ ($\Psi_M(2) = 1$). We have

$$[\Theta_l(K)]^{-1} = \text{Det} \left[1 + \frac{1}{12} [T]^s \right] = \prod_{m=1}^M D(K_m), \quad (29)$$

where $D(K_m)$ is the determinant of the 3×3 matrix

$$D(K_m) = \text{Det} \left[1 + \frac{1}{12} \frac{\partial_{m\alpha} \partial_{m\beta} u(K_m)}{L_\alpha L_\beta} \right]. \quad (30)$$

Further simplifications are possible if the system is cylindrically symmetric, i.e., if $u(K) = u(k_\perp, k_\parallel)$. Then

$$D(K) = A \left[A^2 + A(k_\perp^2 B + \zeta) + k_\perp^2 (B\zeta - C^2) \right], \quad (31)$$

where

$$\begin{aligned} A &= 1 + \frac{1}{12L_\perp^2} \frac{1}{k_\perp} \frac{\partial u}{\partial k_\perp}, & B &= \frac{1}{12L_\perp^2 k_\perp^2} \left[\frac{\partial^2 u}{\partial k_\perp^2} - \frac{1}{k_\perp} \frac{\partial u}{\partial k_\perp} \right], \\ C &= \frac{1}{12L_\perp L_\parallel k_\perp} \frac{\partial^2 u}{\partial k_\parallel \partial k_\perp}, & \zeta &= \frac{1}{12L_\parallel^2} \frac{\partial^2 u}{\partial k_\parallel^2} - \frac{1}{12L_\perp^2} \frac{1}{k_\perp} \frac{\partial u}{\partial k_\perp} \end{aligned} \quad (32)$$

and the correction is given by

$$\Psi_M(3) = \left[\frac{\int \left[e^{-3u(K)} / D(K) \right] dk_\perp^2 dk_\parallel}{\int e^{-3u(K)} dk_\perp^2 dk_\parallel} \right]^M. \quad (33)$$

9 Remarks on size of the region in momentum space

The main difficulty in the measurements is to find a sufficient number of coincidences (to keep the statistical error under control). Therefore it is necessary to limit the size of the region in momentum space where the measurement is performed. This reduces the number of particles and thus increases the probability of coincidence. Below we estimate the practical consequences of this requirement.

9.1 Consequences of boost-invariance

Consider first the longitudinal momentum. If the system is approximately boost-invariant, one expects an approximate linear relation between the considered interval in longitudinal momentum (δK_z) and the size of the corresponding region in the configuration space (L_z , defined as the region from which the emitted particles end up in δK_z):

$$L_z \approx \frac{\delta K_z}{h^2}, \quad (34)$$

where the proportionality coefficient can be approximated by [15]

$$h^2 = \frac{m_\perp}{\tau_0} \quad (35)$$

while m_\perp is the transverse mass of the produced particle and τ_0 is its proper time at freeze-out.

The conclusion is that the size of the selected region in longitudinal momentum determines the size of the corresponding region in configuration space. Consequently, the size of the selected region in longitudinal momentum cannot be too small (if we want the size L_z in z-direction to be large enough for the analysis of this paper to be valid). Note that these remarks do not refer to the choice of the binning (discretization) but to the size of the momentum region in which the measurement is performed⁸.

⁸By an appropriate selection of κ_z , bins can be fixed at will. See the discussion in Section 3.

9.2 Uncorrelated distribution in azimuthal angle

Great improvement in the feasibility of measurement can be obtained if correlations between particles are weak and can be neglected. This is particularly effective if there are no correlations between various segments of the distribution in azimuthal angle. In this case the probability to observe a coincidence in the full azimuthal angle (2π) equals the square of the probability to observe a coincidence in half of the full angle (π). Therefore it is enough to observe the coincidences separately in two regions of size π where the coincidence probability is much larger. Consequently, one needs much fewer events to obtain a decent statistics of coincidences (and thus a decent error of the measurement). The effect can be made even stronger if independence is observed for smaller regions of azimuthal angle. The procedure requires, of course, a careful checking with the data.

10 Numerical estimates

To obtain an idea about the size of corrections $\Lambda_M(l)$ and $\Psi_M(l)$ we shall now explicitly evaluate them in a simplified model where particles are uncorrelated and the single particle momentum distribution is axially symmetric and boost-invariant. The transverse momentum distribution is taken in the Boltzmann form. Thus we have

$$\begin{aligned} w(k_\perp, k_z) d^2 k_\perp dk_z &= A e^{-\sqrt{k_\perp^2 + m^2}/T} d^2 k_\perp dy \\ &= \frac{A e^{-\sqrt{k_\perp^2 + m^2}/T}}{\sqrt{k_\perp^2 + k_z^2 + m^2}} d^2 k_\perp dk_z, \end{aligned} \quad (36)$$

where A is a normalization constant chosen such that $\int w(k_\perp, k_z) d^2 k_\perp dk_z = 1$. Consider first $\Lambda_M(l) = [\lambda(l)]^M$ with

$$\lambda(l) = \frac{\frac{1}{\omega_\perp \delta k_z} \sum_{\text{bins}} \int_{\omega_\perp} d^2 k_\perp e^{-l m_\perp/T} \int_{\delta k_z} \frac{dk_z}{[k_z^2 + m_\perp^2]^{1/2}}}{\left[\frac{1}{[\omega_\perp \delta k_z]^l} \sum_{\text{bins}} \left[\int_{\omega_\perp} d^2 k_\perp e^{-m_\perp/T} \int_{\delta k_z} \frac{dk_z}{\sqrt{k_z^2 + m_\perp^2}} \right] \right]^l}, \quad (37)$$

where

$$\delta k_z = \frac{\sqrt{2\pi}}{[\sqrt{l}]^{1/(l-1)} L_z}, \quad \omega_\perp \equiv \pi \delta k_\perp^2 = \frac{2\pi}{l^{1/(l-1)} L_\perp^2}. \quad (38)$$

In figure 1 the correction factor

$$\delta_2 = \frac{H(2)^{\text{exp}} - H(2)}{H(2)^{\text{exp}}} \quad (39)$$

is plotted as function of L_{\perp}/κ_{\perp} (with κ_{\perp} independent of K) for $L_z = 1$ fm, $\kappa_z = 1$ and two values of T . The longitudinal momentum interval was fixed by $-0.38 \text{ GeV} \leq k_z \leq 0.38 \text{ GeV}$. One sees that for L_{\perp}/κ_{\perp} greater than 1 fm the correction is small.

Figure 1: The correction factor $1 - H(2)/H^{\text{exp}}(2)$ plotted *versus* L_{\perp}/κ_{\perp} with a constant κ_{\perp} and $\kappa_z = 1$. Other parameters are indicated in the figure. One sees that for $L_{\perp}/\kappa_{\perp} \geq 1$ fm the correction is pretty small.

It should be emphasized that, as discussed already in Section 7, the correction factor to H_2 can be fully controlled with a good precision if the bins selected for discretization are small enough. If the size L_{\perp} of the system is small, this can be achieved by a proper choice of the parameter κ . The results shown in figure 1 demonstrate that to this end it is enough to take L_{\perp}/κ_{\perp} larger than 1 fm. Since the measurement of H_2 provides an effective lower limit on the value of the entropy of the system [7], it is reassuring that in this simple way the errors can be minimized and reliably estimated.

For $l \geq 3$ both $\Lambda_M(l) = [\lambda(l)]^M$ and $\Psi_M(l) \equiv [p(l)]^M$ are important. This creates a new problem. Indeed, since the correction factor $\Psi_M(l)$ is insensitive to the bin size, it cannot be eliminated by a proper discretization ($\Psi_M(l)$ does not depend on κ and thus cannot be adjusted at will).

In figure 2 the correction factor

$$\delta_3 \equiv \frac{H(3)^{\text{exp}} - H(3)}{H(3)^{\text{exp}}} \quad (40)$$

Figure 2: The correction factor $1 - H(3)/H^{\text{exp}}(3)$ plotted *versus* L_{\perp} with $\kappa_{\perp} = \kappa_z = 1$.

is plotted *versus* L_{\perp} for $\kappa_{\perp} = \kappa_z = 1$ and for the same parameters as in figure 1. It is seen that the corrections are reasonably small for $L_{\perp} > 1$ fm but become dangerously large for smaller radii. Thus for $l \geq 3$ the method seems safe for heavy ion collisions but cannot be easily justified for systems with linear size smaller than 1 fm.

11 Shannon entropy

The Shannon entropy S (i.e. the standard statistical entropy) is formally equal to the limit of $H(l)$ as $l \rightarrow 1$ and thus can only be obtained by extrapolation from a series of measured values: $H(l) = H(2), H(3), \dots$ to $l = 1$ ⁹. Of course such an extrapolation procedure is not unique and introduces a serious uncertainty [16]. The main point is, as usual, to choose the “best” extrapolation formula, i.e. the functional dependence of $H(l)$ on l which will be used to reach the point $l = 1$ from the measured points $l = 2, 3, \dots$. This form can only be guessed on the basis of physics arguments (or prejudices).

In [2] it was suggested to use

$$H(l) = a \frac{\log l}{l-1} + a_0 + a_1(l-1) + a_2(l-1)^2 + \dots, \quad (41)$$

⁹Obviously, one cannot just put $l = 1$ in the formula (6) for that purpose: since $C(1) = 1$, the r.h.s. of (6) for $l = 1$ represents the undefined symbol $0/0$.

where the number of terms is determined by the number of measured Renyi entropies. This formula turned out to be very effective in reproducing the correct value of entropy for some typical distributions encountered in high-energy collisions.

Another possibility is to use

$$H(l) = a_0 + \frac{a_1}{l} + \frac{a_2}{l^2} + \dots \quad (42)$$

suggested by the formula for the free gas of massless bosons¹⁰.

It will be interesting to compare the results from these two formulae.

Comment: The measured values of the Renyi entropies give valuable information about the system and thus are of great interest, independently of the accuracy of the extrapolation [17]. Moreover, from the inequality [6]

$$S \geq H(l) \geq H(l+1), \quad (43)$$

valid for any $l > 1$, we deduce that a measurement of any Renyi entropy gives an exact lower bound for S . It is well known that this is important information about the quark–gluon plasma [8].

12 Comparison of different regions: Additivity

Measurements of the entropies $H(l)$ and S , as described above, can be performed independently (and — in fact — simultaneously) in different momentum regions. The results should give information on the entropy density and its possible dependence on the region in momentum space (e.g., it seems likely that the results in the central rapidity region may be rather different from those in the projectile or target fragmentation region). Furthermore, it is important to verify to what extent the obtained entropies are additive, i.e., whether the entropies measured in a region R which is the sum of two regions R_1 and R_2 satisfy

$$H(l)(R) = H(l)(R_1) + H(l)(R_2) \rightarrow S(R) = S(R_1) + S(R_2). \quad (44)$$

¹⁰For the free gas of massless bosons the Renyi entropies are given by $H(l) = (1 + 1/l + 1/l^2 + 1/l^3)S/4$ where S is the Shannon entropy [2].

Eq. (44) should be satisfied if there are no strong correlations between the particles belonging to the regions R_1 and R_2 . Thus, verification of (44) gives information about the correlations between different phase-space regions.

Comment: It may be worth pointing out that the additivity (44) can be more precisely tested for Renyi entropies ($H(l)$) than for the Shannon entropy (S), where the extrapolation procedure (described in Section 6) always introduces an additional uncertainty. Since deviations from additivity signal correlations, this is an interesting problem in itself.

13 Conclusions

In conclusion, we have shown that the measurement of Renyi entropies in limited regions of phase-space is feasible and thus important information on the entropy of the system [8, 7] is possible to obtain. Moreover, even the simplest tests of the general scaling and additivity rules can provide essential information on fluctuations and on correlations in the system. It should be emphasized that for these tests the Renyi entropies turn out to be even more useful than the standard Shannon entropy.

We thank K. Fiałkowski and W. Kittel for discussions. This investigation was partly supported by the MEiN research grant 1 P03B 045 29 (2005–2008).

Appendix: Various examples of probability distributions

Distributions with exponential tail

Consider the distribution

$$P(r_i) = U r_i^\alpha e^{-(r_i/a)^\beta} \delta r_i, \quad (45)$$

where δr_i is small, so that we can replace everywhere the summations by integrals. We also assume that $\delta r_i = \text{const} = \delta$. With this assumption the normalization factor U is given by

$$U^{-1} = \int r^\alpha e^{-(r/a)^\beta} dr = \frac{1}{\beta} a^{(\alpha+1)} \Gamma \left[\frac{\alpha+1}{\beta} \right]. \quad (46)$$

The distribution (45) covers a wide range of different distributions. *E.g.*, for $(\alpha = 0, \beta = 2)$ one obtains a Gaussian, for $\beta = 1$ (and arbitrary α), a Gamma distribution (including, as a special case the exponential distribution).

A fairly straightforward calculation gives

$$H(l) = \log \left[\frac{a}{\delta} \frac{\Gamma[(\alpha+1)/\beta]}{\beta} \right] + \frac{1}{\beta} \frac{l\alpha+1}{l-1} \log l - \frac{1}{l-1} \log \left[\frac{\Gamma[(l\alpha+1)/\beta]}{\Gamma[(\alpha+1)/\beta]} \right] \quad (47)$$

and thus

$$S = \log \left[\frac{a\Gamma[(\alpha+1)/\beta]}{\beta\delta} \right] + \frac{\alpha+1}{\beta} - \frac{\alpha}{\beta} \psi[(\alpha+1)/\beta]. \quad (48)$$

In particular, for a Gaussian we have¹¹

$$H_G(l) = \log \left[\frac{a\sqrt{\pi}}{\delta} \right] + \frac{\log l}{2(l-1)}. \quad (49)$$

Power law

$$P(r)dr = \lambda a^\lambda \frac{dr}{(a+r)^{1+\lambda}}, \quad (50)$$

$$C(l) = \lambda^l a^{l\lambda} \delta^{l-1} \int_0^\infty \frac{dr}{(a+r)^{l(1+\lambda)}} = \frac{\lambda^l a^{l\lambda} \delta^{l-1}}{(l\lambda+l-1)a^{l\lambda+l-1}} = \left[\frac{\delta}{a} \right]^{l-1} \frac{\lambda^l}{l\lambda+l-1}, \quad (51)$$

$$H(l) = \log(a/\delta) + \frac{1}{l-1} \log \left(1 + (l-1) \frac{1+\lambda}{\lambda} \right) - \log \lambda, \quad (52)$$

$$S = \log(a/\delta) + \frac{1+\lambda}{\lambda} - \log \lambda. \quad (53)$$

Sum of Gaussians

Consider probability distribution which is a sum of two identical Gaussians separated by distance $2R$. This can be written as

$$P(r) = \frac{1}{a\sqrt{\pi}} \left[\lambda_- e^{-(r+R)^2/a^2} + \lambda_+ e^{-(r-R)^2/a^2} \right], \quad (54)$$

¹¹In this case we take $-\infty \leq r \leq +\infty$. The general formulae (45)–(47) are valid for $0 \leq r \leq +\infty$.

where $\lambda_+ + \lambda_- = 1$, and gives

$$\begin{aligned} C(l) &= \frac{\delta^{l-1}}{[a\sqrt{\pi}]^l} \sum_{j=0}^l \frac{l!}{j!(l-j)!} \lambda_-^j \lambda_+^{l-j} \int dr e^{-j(r+R)^2/a^2} e^{-(l-j)(r-R)^2/a^2} \\ &= \frac{\delta^{l-1}}{[a\sqrt{\pi}]^{l-1} \sqrt{l}} \sum_{j=0}^l \frac{l!}{j!(l-j)!} \lambda_-^j \lambda_+^{l-j} e^{-4R^2 j(l-j)/(la^2)}. \end{aligned} \quad (55)$$

One sees that in the limit of R/a very large, i.e. for well-separated Gaussians, only the terms with $j = 0$ and $j = l$ contribute and we have

$$C(l) = C_G(l) (\lambda_-^l + \lambda_+^l), \quad (56)$$

which simply adds a constant term to the entropy of a single Gaussian.

If $\lambda_- = \lambda_+ = 1/2$, we have $\lambda_-^l + \lambda_+^l = (1/2)^{l-1}$ and thus

$$H(l) = H_G(l) + \log 2. \quad (57)$$

It is not difficult to see that for N well-separated Gaussians one obtains

$$H(l) = H_G(l) - \frac{1}{l-1} \log \left(\sum_{i=1}^N (\lambda_i)^l \right) \quad (58)$$

If all Gaussians have equal weights $l = 1/N$, one obtains

$$H(l) = H_G(l) + \log N \quad (59)$$

This result is valid for any set of well-separated distributions.
